Abstract

Seasonal changes in the pattern of abundance of benthic macro-invertebrates were studied and their correlation with various environmental variables was also estimated. Benthic faunal density was recorded maximum during winter months with Ephemeroptera as the most abundant order at all the sites followed by Plecoptera, Coleoptera, Diptera, Trichoptera, Megaloptera and Odonata. Level of species richness was found dependant on the abiotic factors like temperature, hardness, pH, dissolved oxygen, chlorides and phosphorus. [Life Science Journal. 2007; 4(4): 85 – 89] (ISSN: 1097 – 8135).

Keywords: macro-invertebrates; benthos; Hival stream

1 Introduction

Stream macro-invertebrates have been used extensively for biomonitoring of numerous environmental stresses (Rosenberg and Resh, 1993) and thus have received considerable attention in the study of running water ecosystems (Cummins, 1992). They are sensitive to watershed conditions and exhibit sufficient stability in assemblage structure over time to make them useful as long-term monitors of stream health (Richards and Minshell, 1992) and indicators of water quality (Resh, 1995; Gauffin and Tarzwell, 1952; Wilhm and Dorris, 1968). Hynes (1960) opined that the density of benthos in a water body is a useful index of water quality although density may fluctuate widely with changes in the seasons.

There is practically no data available on limnobioc components of contributing tributaries of Ganga River from Garhwal region and whatever is reported is fragmentary (Sharma *et al.*, 1990; Singh, 1991; Nautiyal, 1986). Considering above facts, present study on sea-

sonal variation of benthic invertebrates and their relation with environmental variables from Hival freshwater stream in Garhwal region of Uttarakhand, India, was undertaken.

2 Materials and Methods

The benthic macro-invertebrates were sampled every month from March, 2005 to February, 2007 at three selected sites of the stream and fourth sample was collected from Ganga River water at Shivpuri to compare and evaluate the benthic macro-invertebrates seasonal variation. Benthic macro-invertebrates were collected by enclosing one square meter area of stream bottom at each site with square meshed cloth. The bottom stones and gravel were upturned to dislodge the aquatic life. Each animal was then brush picked and preserved in 5% formaline and were identified according to Ward and Whipple (1992), APHA (1998) and Pennack (1978) up to the genera level.

Species richness has been calculated on the basis of number of species available at each site. By using the method of least squares and Karl Pearson, the regression equation, coefficient of correlation and standard deviation

tion values between species richness and abiotic factors were calculated using SPSS (version 10).

3 Results

During the period of study, a total of 29 genera belonging to 7 orders of benthic fauna were recorded. The most abundant order having maximum number of genera recorded was Ephemeroptera at each site followed by Plecoptera, Coleoptera, Diptera, Trichoptera, Megaloptera and Odonata. *Baetis* and *Stenonema* sps (Ephemer-

optera), *Acronuria* sps (Plecoptera) and *Psephenus* sps (Coleoptera) were found to be very common at all sites. Figures 1, 2, 3 and 4 postulate the seasonal variation of benthos for the period of study at each site. From the above observations, it is inferred that maximum number of genera in each order were recorded during the winter months followed by summer and monsoon seasons.

The correlation between species richness vs. abiotic factors for each site have been presented in Table 1. A strong negative correlation between species richness and environmental factors like water and air temperature at

site-I ($r = -0.539^{++}$, $r = -0.567^{**}$) and site-III ($r = -0.608^{**}$, $r = -0.574^{**}$) was found. At site-II, a moderate negative correlation between these factors ($r = -0.468^*$, $r = -0.0437^*$) was recorded. pH showed moderate negative correlation at site-III ($r = -0.456^*$) and site-IV ($r = -0.410^*$), however, a strong positive correlation between species richness and hardness at site-I ($r = +0.673^{**}$) and site-IV ($r = +0.583^{**}$) and with chlorides at site-III ($r = +0.554^{**}$) was observed. Phosphorus has strong negative correlation with species richness at site-IV ($r = -0.527^{**}$) and dissolved oxygen showed a positive corre-

lation at site-III ($r = +0.695^{**}$) and site-II ($r = +0.436^*$). Free CO₂, TDS, alkalinity and nitrates did not show any correlation with species richness.

4 Discussion

The maximum density of benthic fauna was observed during winter months, this can be related to the availability of phytoplankton population in the form of food supply as also observed by Joshi *et al* (1996) on Ganga

River. On the other hand decline in the density of benthic fauna during monsoon months may be due to increase load of suspended solids, reduced transparency and

increased water flow. Similar findings have also been observed by many workers (Donald *et al*, 1982; Duffield and Nelson, 1993).

Relationship between macro-invertebrate community structure and environmental variables has been the subject of numerous investigations (Tate and Heiny, 1995; Wright *et al*, 1984; Omerod, 1987; Gower *et al*, 1994). Poff and Ward (1989) identified streamflow variability as a major factor affecting other abiotic and biotic factors that regulate lotic macrozoobenthic patterns.

Brown and Brown (1994) and Richards *et al* (1993) suggested that many variables, including conductivity, dissolved oxygen, pH, current velocity, substrate type, depth and water temperature affect the invertebrate production in response to changes in flow regime.

Hynes (1970) had discussed in general the changes in faunal composition with longitudinal distance in lotic ecosystems and also mentioned oxygen, temperature and nature of substratum as possible contributor to this change.

Pires *et al* (2000) concluded that some of the environmental variables like temperature, conductivity, depth and width influenced the invertebrate distribution and abundance within the Guadiana River Basin. They also reported that Ephemeroptera and Plecoptera were found most abundant at the sites where water quality was good and conditions were acceptable as these groups are sensitive to water quality as contrast to the group Diptera which was associated with poor water quality as they are more resistant to pollution, also observed by Depiereux *et al* (1983). During the present study, most abundant orders recorded are Ephemeroptera and Plecoptera at all sites which indicate good water quality as well as favourable conditions for biotic communities which is in line with the above observation. It is thus concluded that the level of species richness is dependent on the abiotic factors like temperature, hardness, pH, chlorides, phosphorus and dissolved oxygen. However, the importance of habitat types, pollution, biotic factors and anthropogenic activities can not be ruled out.
